Regression Models for Categorical Dependent Variables using Stata: A Comprehensive Guide

160-Character Learn how to build and interpret regression models with categorical dependent variables in Stata. Explore different methods like logit, probit, and multinomial models. Gain practical insights and powerful statistical analysis techniques. **** Regression analysis is a cornerstone of statistical modeling, enabling us to understand the relationship between a dependent variable and one or more independent variables. When the dependent variable is categorical (e.g., success/failure, choice among options), standard linear regression techniques are unsuitable.**

This delves into the application of various regression models for categorical dependent variables using Stata, a powerful statistical software package. We'll explore different models, demonstrate their implementation in Stata, and interpret the results, providing practical examples and visualizations along the way. Binary Logistic Regression **Binary logistic regression is the most fundamental approach for analyzing categorical dependent variables with only two possible outcomes (e.g., yes/no, pass/fail). It models the probability of the event occurring. Instead of directly predicting the categorical outcome, it estimates the log-odds of the outcome.** Formula: $\log(p / (1 - p)) = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_k X_k$ Where: • **p is the probability of the event** • **X₁, X₂, ..., X_k are the independent variables** • **β₀, β₁, β₂, ..., β_k are the estimated coefficients** Interpretation: • **Odds ratio:**

A key interpretation involves the odds ratio, calculated as $\exp(\beta_k)$. This shows how a one-unit change in the independent variable (X_k) impacts the odds of the outcome (p). An odds ratio greater than 1 indicates a positive association, while a value less than 1 signifies an inverse association. Stata

Implementation (Example): *logit success age income education, robust* This command models the probability of "success" (dependent variable) as a function of age, income, and education. The "robust" option accounts for potential heteroskedasticity in the data. Visualization: **[Insert a scatterplot here showing the relationship between age and the probability of success, colored by income, if possible]**

Ordinal Logistic Regression **When the dependent variable has a natural ordering (e.g., customer satisfaction levels: very dissatisfied, dissatisfied, neutral, satisfied, very satisfied), ordinal logistic regression is appropriate. It models the probability of an outcome being in a specific category or below it.** Formula: • **Various link functions are employed depending on the specific model assumptions.** Stata Implementation (Example): *ologit satisfaction age income, link cloglog* **This command models the satisfaction levels using a cumulative log-log link function.**

Multinomial Logistic Regression **If the dependent variable has more than two, unordered categories (e.g., choosing between three brands of coffee), multinomial logistic regression is the appropriate model.**

Formula: • **Different reference categories are specified to create multiple binary logit models.** Stata Implementation (Example): *mlogit brand age income education, refcat(brand1)* This command models

the probability of choosing a specific coffee brand (dependent variable) relative to a reference brand (brand1). Demystifying Regression Models for Categorical Dependent

Variables in Stata

Ever found yourself staring at data where your outcome isn't a neat number, but a choice, a category, or a yes/no? Perhaps you're trying to predict whether a customer will buy a product (yes/no), which treatment a patient will respond to (treatment A, B, or C), or if a loan applicant will default (yes/no). In the world of statistical analysis, these are known as categorical dependent variables, and they require a different approach than the familiar linear regression you might be used to. Fear not, because Stata, that powerhouse of statistical software, has your back!

In this comprehensive guide, we'll dive deep into the fascinating realm of regression models for categorical dependent variables using Stata. We'll demystify the concepts, explore the most common model types, and walk you through how to implement them, interpret their results, and understand their nuances. Whether you're a seasoned researcher or just starting your data analysis journey, this article aims to equip you with the knowledge and practical skills to confidently tackle categorical outcomes in Stata.

Why Standard Linear Regression Falls Short

Before we jump into specialized models, it's crucial to understand why simply plugging categorical data into a standard ordinary least squares (OLS) regression model is a recipe for disaster. OLS assumes that the relationship between your independent variables (predictors) and your dependent variable is linear, and that the errors are normally distributed with constant variance. Categorical outcomes violate these fundamental assumptions.

1. **Non-linearity:** A category like "yes" or "no" doesn't have a linear scale. The difference between "no" and "yes" isn't numerically equivalent to the difference between "yes" and "maybe," for example.
2. **Boundedness:** Predictions from OLS can fall outside the plausible range of your categories (e.g., predict a probability of 1.5 for a binary outcome, which is impossible).
3. **Heteroskedasticity:** The variance of the error terms often changes with the predicted values, violating the assumption of homoscedasticity.

These issues lead to biased estimates, incorrect standard errors, and ultimately, unreliable conclusions. This is where specialized models come into play.

The Workhorses: Binary, Ordinal, and Multinomial Logistic Regression

Stata offers a suite of robust commands to handle different types of categorical dependent variables. The most common ones are based on the logistic distribution, leading to models like logistic regression (also known as logit) and probit regression. While probit uses the cumulative standard normal distribution, logit uses the cumulative logistic distribution. For most practical purposes, they often yield similar results, with logit being slightly easier to interpret in terms of odds ratios.

1. Binary Logistic Regression: The Yes/No Scenario

This is your go-to model when your dependent variable has only two possible outcomes (e.g., employed/unemployed, success/failure, churn/no-churn). The core idea is to model the probability of one of the outcomes occurring as a function of your predictor variables.

The Underlying Principle: Odds and Log-Odds

Instead of directly predicting the probability (which is bounded between 0 and 1), binary logistic regression models the *logarithm of the odds* of the outcome. The odds are the ratio of the probability of an event happening to the probability of it not happening.

$$\text{Odds} = \frac{P(\text{event happens})}{1 - P(\text{event happens})}$$

The log-odds (or logit) is the natural logarithm of the odds:

$$\text{Log-odds} = \ln(\text{Odds})$$

The logistic regression model then postulates a linear relationship between the predictor variables and the log-odds:

$$\ln(\text{Odds}) = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_k X_k$$

Implementation in Stata: The `logit` Command

Stata makes implementing binary logistic regression straightforward with the `logit` command. Let's say you have a dataset where `purchase` is your binary dependent variable (1=yes, 0=no) and `age`, `income`, and `education` are your independent variables.

```
. use "your_data.dta" // Load your dataset
. logit purchase i.income education age, robust
```

Explanation of the command:

- ``logit purchase``: Specifies that `purchase` is your dependent variable and you want to run a logistic regression.
- ``i.income``: The `i.` prefix is used for categorical variables (if `income` is not already a factor variable). Stata will automatically create dummy variables for each category of `income`, with one category serving as the reference group.
- ``education age``: These are your continuous independent variables.
- ``, robust``: This option is highly recommended! It tells Stata to calculate robust standard errors, which are less sensitive to violations of the homoscedasticity assumption. This is a common practice when dealing with logistic regression.

Interpreting the Output: Odds Ratios are Key

The output of the `logit` command can seem daunting at first, but the key to interpretation lies in the odds

ratios. Stata typically presents the results as coefficients (beta values). To get the odds ratios, you can use the ``or`` option:

```
. logit purchase i.income education age, robust or
```

An odds ratio greater than 1 indicates that an increase in the predictor variable (or a move to a higher category for categorical predictors) is associated with an increased odds of the outcome occurring. An odds ratio less than 1 indicates a decreased odds.

For example, if the odds ratio for ``age`` is 1.05, it means that for every one-year increase in age, the odds of purchasing the product increase by 5% (holding other variables constant).

Pro-tip: You can also use ``margins`` command after ``logit`` to estimate predicted probabilities for specific groups or values of your predictors. This can be more intuitive than odds ratios for conveying substantive effects.

2. Ordinal Logistic Regression: When Categories Have an Order

What if your dependent variable has more than two categories, and these categories have a natural order? Think about customer satisfaction levels (e.g., "very dissatisfied," "dissatisfied," "neutral," "satisfied," "very satisfied") or Likert scales. In such cases, ordinal logistic regression (also known as ordered logit) is the appropriate choice.

The Proportional Odds Assumption

The core assumption of ordinal logistic regression is the "proportional odds" assumption. This means that the effect of each predictor variable on the odds of moving from a lower category to a higher category is the same across all cut-points between categories.

Implementation in Stata: The ``ologit`` Command

Stata provides the ``ologit`` command for ordinal logistic regression. Let's assume ``satisfaction`` is your ordinal dependent variable (coded 1 to 5) and ``loyalty_score`` and ``customer_service_calls`` are your predictors.

```
. use "customer_data.dta"
. ologit satisfaction i.customer_service_calls loyalty_score, robust
```

Explanation:

1. ``ologit satisfaction``: Specifies ``satisfaction`` as the ordinal dependent variable.
2. ``i.customer_service_calls``: Treats ``customer_service_calls`` as categorical.
3. ``loyalty_score``: A continuous predictor.
4. ``, robust``: Again, for robust standard errors.

Interpreting the Output: Coefficients and Cut-points

The ``ologit`` output will show coefficients for your predictor variables and also "cut-points" or "thresholds." The coefficients represent the change in the log-odds of moving to a *higher* category for a one-unit increase in the predictor, assuming the proportional odds assumption holds. The cut-points define the boundaries between the categories.

Interpreting these coefficients can be a bit trickier than with binary logit. You're essentially looking at how predictors influence the odds of being in a higher category versus being in a lower category.

Testing the Proportional Odds Assumption: It's crucial to test if the proportional odds assumption is met. Stata has a command for this, often used with ``estat gof`` or by fitting separate models for each cut-point (though this can be computationally intensive).

3. Multinomial Logistic Regression: When Categories Don't Have an Order

What if your dependent variable has three or more categories, and there's no inherent order between them? Consider choices like preferred mode of transportation (car, bus, train, bike), preferred brand of cereal, or political party affiliation. This is where multinomial logistic regression comes in.

The Reference Category Matters

Multinomial logistic regression models the probability of belonging to each category relative to a chosen *reference category*. For each category (except the reference), it estimates a separate set of coefficients, essentially running multiple binary logistic regressions simultaneously.

Implementation in Stata: The ``mlogit`` Command

Stata's ``mlogit`` command is used for this purpose. Imagine you're analyzing ``transport_mode`` (car, bus, train) and want to predict it using ``income`` and ``household_size``.

```
. use "transport_data.dta"  
. mlogit transport_mode i.income household_size, base(1) robust
```

Explanation:

1. ``mlogit transport_mode``: Specifies ``transport_mode`` as the multinomial dependent variable.
2. ``i.income``: Treats ``income`` as categorical.
3. ``household_size``: A continuous predictor.
4. ``base(1)``: This crucial option specifies that category 1 of ``transport_mode`` is your reference category. Stata will estimate the effects of predictors on the odds of choosing other modes relative to the reference mode.
5. ``, robust``: For robust standard errors.

Interpreting the Output: Comparisons to the Reference

The ``mlogit`` output will present coefficients for each predictor *for each non-reference category**. These coefficients represent the change in the log-odds of being in that specific category compared to the reference category, for a one-unit increase in the predictor.

Again, using the ``or`` option can be helpful:

```
. mlogit transport_mode i.income household_size, base(1) robust or
```

An odds ratio greater than 1 for a specific category indicates that the predictor increases the odds of choosing that category relative to the reference category.

Key takeaway: Always be mindful of your ``base()`` category when interpreting ``mlogit`` results.

Beyond the Basics: Other Important Considerations

While binary, ordinal, and multinomial logistic regression are the cornerstones, several other aspects are vital for robust analysis.

Choosing the Right Model: A Decision Tree

The first step is always to determine the nature of your dependent variable:

1. **Two categories?** Binary logistic regression (``logit`` or ``probit``).
2. **Three or more categories, with an order?** Ordinal logistic regression (``ologit``).
3. **Three or more categories, without an order?** Multinomial logistic regression (``mlogit``).

Model Fit and Goodness-of-Fit Tests

Just like with linear regression, you want to assess how well your model fits the data. Stata offers various goodness-of-fit statistics for these models:

1. **Pseudo R-squared:** Several types exist (McFadden, Cox & Snell, Nagelkerke). They provide a general indication of model fit but should be interpreted with caution as they don't have the same direct interpretation as R-squared in OLS.
2. **Likelihood-Ratio Tests:** Compare the model with predictors to a null model (intercept only) to see if the predictors significantly improve the fit.
3. **Hosmer-Lemeshow Test:** Particularly useful for binary logistic regression, it assesses whether the observed and predicted event rates are similar across deciles of risk.

You can access many of these using commands like ``estat ic`` (for information criteria like AIC and BIC) and ``estat gof`` (for Hosmer-Lemeshow).

Handling Overdispersion

In some count data or binary data contexts, you might encounter overdispersion – where the variance is larger than expected by the model. For count data, Poisson and Negative Binomial models are common, but for binary/categorical outcomes, the presence of overdispersion might suggest issues with the model specification or require specialized techniques beyond standard logit.

Interaction Effects and Non-linear Relationships

Just as in OLS, you can include interaction terms to explore how the effect of one predictor changes with the level of another. Stata allows you to specify these in ``logit``, ``ologit``, and ``mlogit`` commands. For instance, ``logit y x1 i.x2#c.x3`` would include an interaction between the categorical variable ``x2`` and the continuous variable ``x3``.

Predicted Probabilities and Marginal Effects

While odds ratios are fundamental, understanding predicted probabilities for specific scenarios can be more intuitive. The ``margins`` command in Stata is incredibly powerful for this:

```
. // After running logit, ologit, or mlogit
. margins, dydx(age income) // Calculate marginal effects of age and
income
. margins, at(age=30 income=50000) // Predict probability at specific
values
```

Marginal effects tell you the change in the predicted probability of the outcome for a one-unit change in a predictor, holding other variables at their means or specified values. This offers a more direct interpretation of the substantive impact of your variables.

Choice Modeling and Discrete Choice Models

In fields like econometrics and marketing, these models are often referred to as discrete choice models. ``mlogit`` is a foundational tool for this, and Stata offers extensions for more complex choice situations, such as nested logit or mixed logit models, if your data structure warrants it.

Stata provides a comprehensive and user-friendly environment to implement and interpret a variety of models, from the ubiquitous binary logistic regression to the more nuanced ordinal and multinomial logistic models.

So, next time you encounter a "yes/no," a "low/medium/high," or a "brand A/B/C" outcome, don't shy away. Embrace the power of Stata's regression models for categorical dependent variables and let your data tell its full story!

Regression Models for Categorical Dependent Variables Using Stata offer a powerful toolkit for researchers and analysts aiming to understand relationships where the outcome is not continuous but instead falls into distinct categories. Unlike linear regression, which assumes a continuous outcome, these models are specifically designed to handle dependent variables that take on discrete values—such as binary choices, ordinal rankings, or nominal classifications. Among the most widely used approaches are logistic regression for binary outcomes, multinomial regression for unordered categories, and ordinal regression for ordered categories, all implementable efficiently in Stata with robust estimation and diagnostic tools.

Understanding Categorical Dependent Variables and the Role of Stata

Categorical dependent variables are pervasive across disciplines, from healthcare researchers predicting disease presence (yes/no) to marketers assessing customer satisfaction on a Likert scale. Modeling such outcomes requires methods that respect the non-continuous nature of the data, ensuring accurate probability estimates and meaningful inference. Stata, with its extensive statistical capabilities and user-friendly interface, stands out as a premier platform for fitting these models. Its built-in commands enable users to specify model types, handle complex data structures, and perform advanced diagnostics—all while delivering precise output for research validation.

A primary application of regression models for categorical outcomes is binary logistic regression, which estimates the probability of a binary event occurring based on predictor variables. For example, in medical studies, researchers might use this model to assess how patient characteristics influence the likelihood of developing a condition. Stata's command simplifies model estimation, automatically computing odds ratios, confidence intervals, and goodness-of-fit statistics, making it accessible for both beginners and seasoned analysts. When outcomes involve more than two unordered categories—such as classifying customer preferences into "low," "medium," or "high" satisfaction levels—the multinomial logistic model becomes essential. Stata's command extends the analysis by estimating separate logits for each category relative to a reference group, enabling nuanced interpretation of how predictors shift category probabilities. This flexibility supports deeper insights into preference patterns and decision-making processes across diverse fields.

For ordered categorical variables—where categories have a natural sequence like educational attainment or pain severity—ordinal logistic regression offers an appropriate framework. Stata's command efficiently fits these models under the proportional odds assumption, allowing analysts to

evaluate how predictors influence cumulative probabilities across ordered levels. When assumptions are challenged, alternative models such as partial proportional odds can be explored, ensuring robust and reliable results.

Advantages and Practical Benefits of Using Stata

One of the most compelling benefits of Stata for categorical regression is its comprehensive approach to model diagnostics and validation. After fitting a regression, users gain immediate access to key metrics—such as AIC, BIC, and likelihood-ratio tests—facilitating model comparison and selection. The software supports robust standard errors and provides tools for detecting multicollinearity, influential observations, and overdispersion, helping ensure model reliability and validity. Stata also excels in handling complex survey data and panel structures, making it ideal for applied research involving clustered or longitudinal categorical outcomes. Researchers can incorporate fixed and random effects seamlessly, supporting nuanced analyses of repeated measures or hierarchical data. The integration of graphical tools further enhances interpretation, allowing users to visualize predicted probabilities and residual patterns—critical for assessing model fit beyond numerical summaries.

Another significant advantage is Stata's balance between accessibility and depth. While its syntax and command structure are intuitive for new users, the depth of functionality supports advanced modeling techniques. Whether exploring interaction effects, non-linear relationships, or Bayesian approaches via extensions, Stata empowers researchers to tackle the full spectrum of categorical regression challenges with confidence.

The Future of Categorical Regression with Stata

As data complexity grows, so does the demand for flexible and scalable analytical methods. Stata continues to evolve, incorporating machine learning integrations and enhanced computational performance to handle large categorical datasets efficiently. Future developments may expand support for emerging modeling paradigms such as generalized additive models for categorical outcomes or ensemble methods tailored to discrete responses. Moreover, the emphasis on reproducibility and transparent reporting within Stata aligns with modern scientific standards. By enabling detailed documentation and automated reporting through built-in tools, Stata supports rigorous, replicable research—essential for advancing knowledge in fields reliant on categorical dependent variables. As analytical needs expand across medicine, social sciences, and business analytics, Stata remains a trusted, future-ready platform for mastering regression models tailored to categorical outcomes.

In summary, regression models for categorical dependent variables using Stata provide a comprehensive, reliable, and accessible foundation for analyzing discrete outcomes. From foundational logistic and multinomial models to advanced ordinal frameworks, Stata delivers the precision and depth required to extract meaningful insights, supporting robust research and informed decision-making across disciplines.

Unlocking Insights: Regression Models for Categorical Dependent Variables in Stata

In the realm of statistical analysis, understanding and predicting outcomes is paramount. While continuous dependent variables have long been the focus of regression analysis, many real-world phenomena involve outcomes that fall into distinct categories. Whether predicting customer churn (yes/no), disease status (healthy/sick), or voting preference (party A/party B/party C), the nature of the dependent variable dictates the appropriate modeling approach. Stata, a powerful statistical software package, offers a robust suite of tools for tackling these challenges, particularly through its comprehensive implementation of regression models for categorical dependent variables. This article delves deep into these models, exploring their theoretical underpinnings, practical applications, and essential implementation within Stata.

The Nature of Categorical Data and Why Standard Regression Fails

Categorical dependent variables, by definition, represent discrete groups or classes. They can be further classified into two main types: nominal and ordinal. Nominal variables have no inherent order (e.g., color, marital status), while ordinal variables possess a natural ranking (e.g., education level, satisfaction rating). Standard linear regression, which assumes a continuous and normally distributed dependent variable, fundamentally breaks down when applied to categorical outcomes. The assumptions of linearity, constant variance, and normality are violated, leading to biased estimates, incorrect standard errors, and unreliable predictions. For instance, predicting a binary outcome with linear regression could yield predicted probabilities outside the meaningful range of 0 to 1, rendering the results nonsensical.

Key Regression Models for Categorical Dependent Variables in Stata

Stata provides a rich set of commands for fitting various regression models tailored for categorical outcomes. The choice of model depends primarily on the number of categories and whether there's an inherent order among them. Here, we explore the most prevalent types:

1. Binary Logistic Regression (Logit): Predicting Dichotomous Outcomes

Perhaps the most ubiquitous model for categorical dependent variables is binary logistic regression, often referred to as logit regression. This model is designed for situations where the dependent variable has only two possible outcomes (e.g., success/failure, employed/unemployed). Instead of directly modeling the probability of the outcome, logit regression models the *log-odds* of that outcome. The log-odds is the natural logarithm of the odds, where odds are defined as the probability of an event occurring divided by the probability of it not occurring.

The fundamental equation in binary logistic regression is:

$$\log(P(Y=1) / (1 - P(Y=1))) = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_k X_k$$

Where:

1. $P(Y=1)$ is the probability of the outcome of interest (e.g., success).
2. β_0 is the intercept.
3. $\beta_1, \beta_2, \dots, \beta_k$ are the coefficients for the predictor variables $X_1, X_2, \dots, X_k$.

In Stata, the primary command for binary logistic regression is `logit`. A typical syntax would be:

```
logit dependent_variable independent_variable1 independent_variable2 ... ,
options
```

Interpreting the coefficients from a `logit` command can be done in several ways. While the coefficients themselves represent the change in the log-odds for a one-unit increase in the predictor, it's often more intuitive to exponentiate them to obtain odds ratios. An odds ratio greater than 1 indicates an increased likelihood of the outcome, while an odds ratio less than 1 suggests a decreased likelihood. Stata provides the `estat ic` command after fitting the model to display these odds ratios directly, or you can use `lincom _b[independent_variable]` to calculate the odds ratio for a specific variable.

LSI Keywords: binary outcome, probability prediction, odds ratio, log-odds, maximum likelihood estimation, medical research, marketing analysis.

2. Probit Regression: An Alternative to Logit

Probit regression is another popular choice for binary dependent variables. It is theoretically similar to logit regression in that it models the probability of an outcome. However, instead of using the logit (logistic) cumulative distribution function, probit regression employs the cumulative standard normal distribution function. This means probit regression models the *z-score* of the probability.

The fundamental equation in probit regression is:

$$\Phi^{-1}(P(Y=1)) = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_k X_k$$

Where:

1. Φ^{-1} is the inverse of the cumulative standard normal distribution function.
2. $P(Y=1)$ is the probability of the outcome of interest.
3. $\beta_0, \beta_1, \dots, \beta_k$ are the coefficients for the predictor variables.

In Stata, the command for probit regression is `probit`. The syntax is analogous to the `logit` command:

```
probit dependent_variable independent_variable1 independent_variable2 ... ,
options
```

While logit and probit models often yield very similar results in practice, especially for large sample sizes, they differ in their underlying distributional assumptions. The choice between logit and probit is often a matter of convention or theoretical preference. Some argue that probit is more theoretically sound if one assumes an underlying latent continuous variable that, when exceeding a certain threshold, leads to the observed binary outcome. Like with `logit`, you can use `estat ic` or `lincom` to interpret coefficients in terms of marginal effects, which represent the change in probability for a unit change in the predictor.

LSI Keywords: normal distribution, latent variable, marginal effects, psychological research, econometrics.

3. Multinomial Logistic Regression: For Unordered Categorical Outcomes

When the dependent variable has more than two categories, and these categories have no inherent order, multinomial logistic regression is the appropriate tool. This model extends the principles of binary logistic regression to analyze situations with multiple, unordered choices.

Multinomial logistic regression models the probability of each category relative to a chosen reference category. For a dependent variable with J categories, it estimates $J - 1$ equations, each modeling the log-odds of a particular category compared to the reference category.

In Stata, the command for multinomial logistic regression is `mlogit`. The syntax is:

```
mlogit dependent_variable independent_variable1 independent_variable2 ... ,  
base(reference_category) options
```

The `base()` option is crucial for specifying the reference category, against which all other categories are compared. The output provides coefficients and odds ratios for each non-reference category relative to the base category. Interpretation focuses on how changes in predictor variables affect the relative likelihood of being in one category versus the reference category.

A key consideration with `mlogit` is the independence of irrelevant alternatives (IIA) assumption. This assumption states that the relative odds of choosing between two alternatives are unaffected by the presence or absence of other alternatives. While a strong assumption, it's often considered reasonable in many applications. Stata offers tests, such as the `mtest` command, to check for violations of the IIA assumption.

LSI Keywords: multiple categories, unordered outcomes, reference category, IIA assumption, choice modeling, survey analysis.

4. Ordinal Logistic Regression (Ordered Logit): For Ordered Categorical Outcomes

When the dependent variable's categories have a natural and meaningful order, ordinal logistic regression is the preferred method. This model leverages the ordered nature of the data to provide more parsimonious and statistically efficient estimates compared to treating the categories as nominal in a multinomial model.

Ordinal logistic regression, often called ordered logit or proportional odds model, models the cumulative probabilities. It assumes that the effect of the independent variables is the same across all thresholds between categories. The core idea is to predict the probability of being in a particular category or a lower category.

In Stata, the command for ordinal logistic regression is `ologit`. The syntax is:

```
ologit dependent_variable independent_variable1 independent_variable2 ... ,  
options
```

The output of `ologit` includes coefficients for the predictor variables and "cutpoints" or "thresholds" that define the boundaries between categories. The coefficients indicate how changes in predictors affect the log-odds of moving to a higher category. The proportional odds assumption is central to this model and can be tested using commands like `oprobit` and its associated post-estimation tests, or by fitting a more general Brant test.

For situations where the proportional odds assumption is violated, Stata offers alternative ordinal models, such as the generalized ordered logit model (`gologit2`, a user-written command). This allows for different coefficients for each threshold, offering more flexibility but requiring more data and potentially leading to a less parsimonious model.

LSI Keywords: ordered categories, cumulative probability, proportional odds, Brant test, Likert scales, satisfaction surveys.

Implementing and Interpreting Models in Stata

Beyond the core commands (`logit`, `probit`, `mlogit`, `ologit`), Stata offers a rich ecosystem of post-estimation commands and options for a comprehensive analysis:

Understanding Model Fit and Goodness-of-Fit Statistics

Assessing how well a model fits the data is crucial. For categorical dependent variable models in Stata, common goodness-of-fit measures include:

1. **Pseudo R-squared:** While not directly interpretable as in linear regression, various pseudo R-squared measures (e.g., McFadden's, Cox & Snell, Nagelkerke) provide a relative indication of model fit. These are typically accessed via `estat ic` or specified within the fitting command.
2. **Likelihood-Ratio (LR) Test:** Comparing a model with predictors to a null model (intercept only) helps determine if the predictors collectively improve the model fit.
3. **Hosmer-Lemeshow Test:** Primarily used for binary logistic regression, this test assesses the calibration of the model by comparing observed and expected event rates across different deciles of predicted probabilities.

Predicting Probabilities and Classifications

Once a model is fitted, Stata allows you to predict probabilities of the outcome for new data or for the existing dataset. The `predict` command, used with appropriate options, is instrumental. For instance:

```
predict probability_of_success, pr
```

This generates a new variable containing the predicted probabilities. You can then set a threshold (e.g., 0.5) to classify observations into predicted categories, which is useful for evaluating classification accuracy.

Marginal Effects: Quantifying the Impact of Predictors

While odds ratios are informative for logit and multinomial logit models, marginal effects often provide a more direct interpretation of the impact of predictor variables on the *probability* of the outcome.

Marginal effects represent the change in the probability of the outcome for a one-unit change in a predictor, holding other predictors constant at specific values (e.g., their means or a specific profile).

Stata's `margins` command is the go-to tool for calculating and displaying marginal effects after fitting models for categorical dependent variables. For example:

```
margins, dydx(independent_variable1)
```

Handling Complex Survey Data

Many datasets with categorical dependent variables arise from complex survey designs. Stata's `svy` prefix is essential for correctly accounting for survey weights, stratification, and clustering in the estimation of standard errors and statistical tests. When using the `svy` prefix, you would precede your model command with `svy:`, e.g., `svy: logit ....` This ensures that the model fitting and subsequent inference are robust to the survey design.

Conclusion

Regression models for categorical dependent variables are indispensable tools for researchers across a multitude of disciplines. Stata, with its user-friendly interface and powerful statistical engine, provides a comprehensive and flexible environment for applying these models. From understanding the binary choices of individuals to predicting outcomes across multiple ordered or unordered categories, Stata's commands and post-estimation features empower analysts to derive meaningful insights, test hypotheses rigorously, and make informed predictions. By mastering the nuances of binary logit, probit, multinomial logit, and ordinal logistic regression in Stata, researchers can effectively unlock the secrets hidden within their categorical data and contribute to a deeper understanding of complex phenomena.

Questions & Answers About regression models for categorical dependent variables using stata

No	Question	Answer
1	What's the go-to Stata command for running a logistic regression when my outcome is binary?	For a binary dependent variable, the command you'll most frequently use in Stata is <code>`logit`</code> . For example, <code>`logit outcome_variable independent_variable1 independent_variable2`</code> .
2	I have a categorical outcome with more than two unordered options. What Stata command should I use instead of <code>`logit`</code> ?	When your dependent variable has three or more unordered categories, you'll typically use <code>`mlogit`</code> in Stata. The syntax is similar, specifying your outcome variable followed by your predictors. For example, <code>`mlogit outcome_variable independent_variable1`</code> .
3	How do I interpret the coefficients from a logistic regression in Stata?	Coefficients from <code>`logit`</code> are interpreted as the change in the log-odds of the outcome for a one-unit change in the predictor. To get more intuitive odds ratios, use the <code>`or`</code> option: <code>`logit outcome_variable predictors, or`</code> .
4	What's the difference between <code>`logit`</code> and <code>`probit`</code> in Stata, and when should I choose one over the other?	<code>`logit`</code> assumes a logistic distribution for the error term, while <code>`probit`</code> assumes a normal distribution. In practice, they often yield very similar results for binary outcomes. <code>`logit`</code> is more common for its easier interpretation in terms of odds ratios.
5	I have an ordinal outcome variable (e.g., low, medium, high). What Stata command is best suited for this situation?	For ordinal dependent variables, use the <code>`ologit`</code> command in Stata. It accounts for the ordered nature of the categories. Example: <code>`ologit outcome_variable independent_variable1`</code> .
6	After running a <code>`logit`</code> or <code>`mlogit`</code> in Stata, how can I predict the probability of an outcome for specific values of my predictors?	You can use the <code>`predict`</code> command after your regression. For example, after <code>`logit`</code> , <code>`predict predicted_probability, pr`</code> will store the predicted probabilities. You can then use <code>`margins`</code> to calculate predicted probabilities for specific predictor values.
